Abstract. In this paper we consider the problem of learning hidden independent cascade social networks using exact value injection queries. These queries involve activating and suppressing agents in the target network. We develop an algorithm that optimally learns an arbitrary social network of size n using $O(n^2)$ queries, matching the information theoretic lower bound we prove for this problem. We also consider the case when the target social network forms a tree and show that the learning problem takes $\Theta(n \log(n))$ queries. We also give an approximation algorithm for finding an influential set of nodes in the network, without resorting to learning its structure. Finally, we discuss some limitations of our approach, and limitations of path-based methods, when non-exact value injection queries are used.

1 Introduction

Social networks are used to model interactions within populations of individuals. These interactions could include distributing information, spreading a disease, or passing trends among friends. Viral marketing is an often used example of a process well modeled by social networks. In viral marketing, a company may want to market a product to some population. The idea is to carefully choose some people to target. This can be done, for instance, by giving these people a free sample of the product. The targeted people have relationships in their population, and they will possibly virally spread interest in this product to their friends, and so on.

Social networks are often used to describe this type of phenomenon, and there are many different models of social networks. All of these models (imperfectly) approximate these complicated real world phenomena. One of the most basic and well-studied models is the **independent cascade model** [6, 9, 10], and it is the one we consider in this paper. Informally, in the independent cascade model each individual, or agent, has some probability of influencing each other agent. When an agent is targeted with a product, he becomes activated, and then attempts to influence each of his friends, and so on. This model is called independent cascade

because each agent’s success probability in attempting to influence a friend is independent of the history of previous activation attempts in the network.

Social networks belong to the wider class of probabilistic networks. Probabilistic networks are circuits whose gate functions specify, for each combination of inputs, a probability distribution on the output. In the case of social networks, these gates compute rather simple functions of their inputs.

A natural question to ask is: what can we learn about the structure of these networks by experimenting with their behavior? Given access to a pool of agents in our network, one intuitive way in which we could experiment on this network would be to artificially excite some set of agents, for example by sending them political brochures in support of some measure, and then observe the consequences of the experiment. Furthermore, we will allow for the possibility of suppressing agents; when an agent is suppressed, he cannot be excited by another agent. To make things more realistic, and theoretically more interesting, we will not assume that we can observe the entire network. We will instead have an output agent, whose state at the end of this process we can see, for example the probability the president supports the measure.

Thus, in this paper we consider the setting where we can **inject values** into the network; we fix the states (or values) of any subset of agents in the target network and only observe the state of some specified agent, whom we think of as the output of the network. This is the value injection query model.

The idea of value injection queries was inspired both from hardness results in learning circuits by only manipulating inputs [5,8,11] and by models of gene suppression and gene overexpression in the study of gene interaction networks [1,7] and was proposed by Angluin et al [4]. They show that acyclic deterministic boolean circuits with constant fan-in and $O(\log n)$ depth are learnable in polynomial time with value injection queries. Angluin et al. [3] extend these results to circuits with polynomial-size alphabets. They show that transitively reduced acyclic deterministic circuits that have polynomial-size alphabets, constant fan-in, and no depth bound are learnable in polynomial time with value injection queries. Then, Angluin et al. [2] extend this work to probabilistic circuits. They show that constant fan-in acyclic boolean probabilistic circuits of $O(\log(n))$ depth can be approximately learned in polynomial time, but that this no longer necessarily holds once the alphabet becomes larger than boolean.

However, unlike in previous work on the value injection model, we allow our target social networks to have cycles. In many classes of networks, allowing for cycles would make the problem ill-defined in the value injection model, as the values on the nodes of the network may not be stable. In the social networks case, the values of the nodes in the network converge. Also, unlike in previous work, our learnability results do not require a degree bound on the target network. This gives us a nice theoretical model whose properties are interesting to explore.

In Section 2 we formally define the model, value injection queries, and learning criteria. In Section 3 we develop an algorithm that learns any social network in $O(n^2)$ queries and prove a matching lower bound for this problem. In Section 4 we show that in the special case when the network comes from the class

of trees, learning the network takes $\Theta(n \log(n))$ queries. In Section 5 we show some limitations of using path-based methods for learning social networks when value injection queries do not return exact probability distributions of value of the output node, which is the case in real-world settings. In Section 6 we give an approximation algorithm for learning influential sets of nodes in a social network.

2 Model

2.1 Social Networks

We consider a class of circuits that represents social networks. We are specifically interested in a variant of the model of deterministic circuits defined in [3,4]. The social networks have no distinguished inputs – instead, value-injection experiments may be used to override the values on any subset of the agents.

An **independent cascade social network** S consists of a finite nonempty set of independent excitation agents A , one of which is designated as the **output agent**. Agents take values from a boolean alphabet $\Sigma = \{0, 1\}$, corresponding to the states *waiting* and *activated*, respectively. The size of the social network is $n = |A|$.

An **independent excitation** agent function f on k inputs has k parameters: the probabilities p_1, \dots, p_k . If the inputs to the agent are $(b_1, \dots, b_k) \in \{0, 1\}^k$, then the probability that $f(b_1, \dots, b_k)$ is 0 is

$$\prod_{i=1}^k (1 - p_i)^{b_i}.$$

We define $0^0 = 1$.

If we are told, in an arbitrary order, which inputs to f are 1, then we may sample from the correct output distribution for f as follows. Initially the output is 0. Given that $b_i = 1$, then with probability p_i we set the output to 1 and with probability $(1 - p_i)$ we leave it unchanged. This corresponds to our intuitive notion of the behavior of social networks; when a neighbor of an agent is activated, the agent has some probability of becoming activated as well, and an agent will remain inactive if it was not activated by any of its neighbors.

2.2 Graphs of Social Networks

The weighted **network graph** of the social network has vertices A and a directed edge (u, v) if agent u is one of the inputs of agent v . If u is an input to v with activation probability $p_{(u,v)}$, then the edge has weight $p_{(u,v)}$. We say an edge exists if it has positive weight. The weighted network graph of a social network captures all relevant information about the social network. Therefore, we will often refer to a social network in terms of its graph. The **depth** of a node in the network is the number of edges in the shortest path from the node to the output. The depth of the network is the maximum over the depths of all the

nodes in the network. The network is **acyclic** if the network graph contains no directed cycles. Unlike in previous work on value injection queries, in this paper we consider networks that may have cycles.

2.3 Experiments

The behavior of a social network consists of its responses to all possible value-injection experiments. In an experiment, some agents are fixed to values from $[0, 1]$ and others are left free. Fixing an agent to a 1 corresponds to **activating** or **firing** the agent, fixing to a 0 corresponds to **suppressing** the agent, and leaving an agent **free** allows it to function as it normally would. Fixing an agent to a value c between 0 and 1 corresponds to firing the agent with probability c and suppressing it with probability $1 - c$.

Formally, a **value-injection experiment** (or just experiment) e is a mapping from A to $\{[0, 1] \cup \{*\}\}$. If $e(g)$ is $*$, then the experiment e leaves agent g **free**; otherwise g is **fixed** to the value $e(g) \in [0, 1]$. If e is any experiment and $a \in [0, 1] \cup \{*\}$, the experiment $e|_{w=a}$ is defined to be the experiment e' such that $e'(w) = a$ and $e'(u) = e(u)$ for all $u \in A$ such that $u \neq w$.

We can define the behavior of a social network S as a function of a value-injection experiment in two different ways. The first is a percolation model. For each edge (u, v) , we leave it “open” with probability $p_{(u,v)}$ and “closed” with probability $1 - p_{(u,v)}$. For each node w in S , such that $e(w) = c$ for some $c \in [0, 1]$, we make node w fired with probability c and suppressed with probability $1 - c$. We let the indicator variable $I = 1$ if there is direct path using open edges from some fired node to the output node via free nodes, and we let $I = 0$ otherwise. This determines a probability distribution on assignments of 0 and 1 to I . We define the output $S(e)$ to be $E(I)$.

The following process, equivalent to the percolation model, defines the behavior of social network as a function of a value-injection experiment e . It is also the process that will guide the intuition and proofs in this paper. Initially every node is tentatively assigned the value 0. There is a queue of nodes to be assigned values, which initially contains the nodes fixed to values > 0 by e . The assignments are complete when the queue becomes empty. While the queue is nonempty, its first node v is dequeued. If $e(v) = *$, v is assigned the value 1. If $e(v) \neq *$, v is assigned a 1 with probability $e(v)$, and 0 with probability $(1 - e(v))$. If v is assigned a 1, for every node u such that v is an input to u , do the following.

1. If u is fixed to any value, or already assigned 1 or present in the queue, do nothing.
2. Otherwise, with probability $p_{(v,u)}$ add u to the queue, and with probability $(1 - p_{(v,u)})$ do nothing.

This process determines a joint probability distribution on assignments of 0 and 1 to the nodes of the social network S . In this case, the output $S(e)$ is the expected value of the output node given by e .

2.4 Behavior and Equivalence

The **behavior** of a network is the function that maps experiments e to output excitation probabilities $S(e)$. Two social networks S and S' are **behaviorally equivalent** if they have the same set of agents, the same output agent, and the same behavior, that is, if for every value-injection experiment e , $S(e) = S'(e)$. We also define a concept of approximate equivalence. For $\epsilon \geq 0$, S is **ϵ -behaviorally equivalent** to S' if they contain the same agents, the same output agent and for every value-injection experiment e , $|S(e) - S'(e)| \leq \epsilon$.

2.5 Queries

The learning algorithm gets information about the target network by repeatedly specifying an experiment e and observing the value assigned to the output node. Such an action is termed a **value injection query**. A value-injection query does not return $S(e)$, but instead returns a $\{0, 1\}$ value selected according to the probability $S(e)$. This means that the learner must repeatedly sample to approximate $S(e)$. To separate the effects of this approximation from the inherent information requirements of this problem, we define an **exact value injection query** to return $S(e)$. The focus of this paper is on exact value injection queries.

2.6 The Learning Problem

The learning problem we consider is: by making exact value injection queries to a target network S drawn from a known class of social networks, find a network S' that is behaviorally equivalent to S . The inputs to the learning algorithm are the names of the agents in S and the name of the output agent.

To help with terminology, let S be a social network. Let S' be any social network that differs only in edge (u, v) . We say edge (u, v) is **discoverable** for S if there exists an experiment e such that $S(e) \neq S'(e)$. Otherwise we say that the edge is not discoverable. We could also view the learning problem in terms of finding the discoverable edges and their probabilities.

2.7 A Note on the Generality of This Model

The model introduced in this section allows for the observation of the network by looking at the output of one selected node. However, this model is surprisingly general. One may wish to consider, for example, the ability to observe the number of nodes to fire as a result of an experiment. Such a scenario could be simulated in our model – given any social network, one could make a new output node that is activated by each node with some fixed, chosen probability. Now the probability the output is activated corresponds to the number of network nodes that are activated in an experiment.

One could also imagine networks where some nodes spontaneously fire with some probability. We can again simulate this in the model we introduced. We add a node that is fired with probability 1 whenever any node in the network

fires (all other nodes have 1-edges to the new node), and the new node can have edges to each node in the network, with probabilities corresponding to the desired spontaneous firing probabilities of the network nodes.

3 General Social Networks

In this section we prove the following theorem.

Theorem 1. *Any social network with n agents can be learned up to behavioral equivalence with $O(n^2)$ exact value injection queries and time polynomial in the number of queries.*

First, we develop excitation paths, which are a variant of test paths, a concept central in previous work on learning deterministic circuits [3, 4]. An **excitation path** for an agent a is a value-injection experiment in which a subset of the free agents form a simple directed path¹ in the circuit graph from (but not including) a to the output agent. All agents not on the path with inputs into the path are fixed to 0. A **shortest excitation path** is an excitation path of length equal to the depth of a .

Let G be the network graph of A . In G , the **up edges** are edges from nodes of larger depth to nodes of smaller depth, **level edges** are edges among nodes of the same depth, and **down edges** are edges from nodes of smaller depth to nodes of larger depth. An edge (u, v) is a **shortcut edge** if there exists a directed path in G of length at least two from u to v .

Lemma 1. *Let e be a shortest excitation path for node a and π be the nodes on the path. Let $p_1 \cdots p_k$ be the weights of the up edges in $\pi \cup a$. Then for $0 \leq c \leq 1$*

$$S(e|_{a=c}) = c \prod_{i=1}^k p_i.$$

Proof. In a shortest excitation path, if some node on the path does not activate, no node at smaller depth will activate, because a shortest excitation path cannot have shortcuts to nodes further along the path. Hence, all up edges must fire to fire the output. This happens exactly with probability $\prod_{i=1}^k p_i$. We note that this lemma still holds when a takes probability c , not only when its set to c by e . \square

Lemma 2. *Let e be an excitation path experiment for node v and let $\pi = v_k, \dots, v_0$ be the nodes along π in order from v to the output (with v_0 being the output node), such that there are no shortcut edges (v_i, v_j) for $j < i$ along π . Let $u \notin \pi$ be a node such that all edges from u to nodes on π are known and have weights < 1 . Let $e' = e|_{v=*, u=1}$. Then, given $S(e')$ we can compute $p_{(u,v)}$.*

¹ A path with no repeated vertices is called simple.

Proof. We observe that because there are no shortcuts along π , no node v_i will activate in e' unless either u activated it, or v_{i+1} . Hence, any edge (v_j, v_k) where $j < k$ does not affect $S(e')$. Therefore, we can compute $S(e')$ by summing over all the ways v_0 can activate. Either u activates it directly with probability $p_{(u,v_0)}$, or if not (with probability $1 - p_{(u,v_0)}$) we look at the probability u activates v_1 and the probability of v_1 firing the output, and so on. These quantities can be computed using the logic of Lemma 1. For the calculation below, we rename node v to v_{k+1} .

$$S(e') = \sum_{i=0}^{k+1} \left(p_{(u,v_i)} \prod_{j<i} (1 - p_{(u,v_j)}) (p_{(v_{j+1},v_j)}) \right)$$

This equation is linear in $p_{(u,v_{k+1})}$, which we can solve for because the other quantities are known. \square

We now present Algorithm 1 for learning social networks.

Algorithm 1 Learning Arbitrary Social Networks

Let S be the target social network.
Initialize G to have the agents as vertices and no edges.
Run **Find-Up-Edges** to learn the leveled graph of S .
Add learned weighted edges to G .
Let $C = \emptyset$ be the complete set.
for Each level i in the graph, from the deepest level to the output node **do**
 Run **Find-Remaining-Edges**(G, C, i) to learn all level and down edges.
 Add all nodes at the current level to C .
end for
Output G and halt.

The subroutine **Find-Up-Edges** builds a leveled graph of S . Let **level** i be the set of all nodes at depth i . Find-Up-Edges assigns each node to a level and finds all up edges in the graph. Starting at the top level and proceeding downward, for each pair of nodes u and v , such that u is one level deeper than v , Find-Up-Edges finds a shortest excitation path for u that goes through v to learn $p_{(u,v)}$. This experiment leaves the path free and suppresses all other nodes in the graph. We show correctness by induction on the level. For the base case, the edges from nodes at depth 1 form the paths. Considering nodes at depth i we assume we know all up edges on the induced subgraph at depths 0 to $i - 1$. Therefore, for each node at depth $i - 1$ we have a shortest excitation path to the root. Thus, for each node u not yet assigned a level, we can try experiments with excitation paths via each node v at depth $i - 1$. Let e be such an experiment with π as the excitation path. And let $p_1 \cdots p_{i-1}$ be the weights of the up edges in π . By Lemma 1 we can compute

$$p_{(u,v)} = \frac{S(e|_{u=1})}{\prod_{j=1}^{i-1} p_j}.$$

If $p_{(u,v)} > 0$ we assign node u to level i .

After Find-Up-Edges is run, the remaining edges that need to be found are down and level edges. The subroutine **Find-Remaining-Edges**, shown in Algorithm 2, accomplishes this task. The algorithm keeps a complete set C in which all discoverable edges are known. C starts at the largest level and grows toward smaller levels. Find-Remaining-Edges finds all discoverable edges from the level it is on to the complete set. It also finds all discoverable edges between nodes at the level it is on. Then, that level is added to C .

Algorithm 2 Find-Remaining-Edges(Current Graph G , Complete Set C , Level i)

Let L be the set of nodes at the current level i .
 Let $M = L \cup C$.
 Let Π be a collection of paths.
 Keep an $|L|$ by $|M|$ table T . $\forall w_i \in L, x_j \in M$ s.t. $w_i \neq x_j, T(w_i, x_j) = 1$.
loop
 Set $\Pi = \emptyset$.
 for Each node $w_i \in L$ **do**
 Find A_{w_i} , the set of all nodes reachable from w_i by 1-edges (incl. w_i) in G .
 for Each node $x_j \in M$ where $T(w_i, x_j) = 1$ **do**
 Find the shortest path π_{w_i, x_j} in $G - A_{w_i}$ from x_j to the root.
 $\Pi = \Pi \cup \pi_{w_i, x_j}$.
 end for
 end for
if $\Pi = \emptyset$ **then return**.
 Let w_i, x_j minimize the length of $\pi_{w_i, x_j} \in \Pi$.
 Let experiment e fire w_i , leave π_{w_i, x_j} free, and suppress the rest of the nodes.
 Query $S(e)$ and compute $p_{(w_i, x_j)}$ by Lemma 2.
 Set $T(w_i, x_j) = 0$.
If $p_{(w_i, x_j)} > 0$ **then** add (w_i, x_j) to G .
end loop

Let L be the set of nodes on level i . To find down and level edges from nodes in L , Find-Remaining-Edges keeps a table T , with an entry for each possible edge originating from a node in L . Each entry is initially set to 1. After determining whether an edge is present, its corresponding entry becomes marked 0. The potential edges whose corresponding entries are marked 1 we call “unprocessed.”

For each unprocessed edge (u, v) , we find the set of all nodes we know are guaranteed to be activated when u is fired. This is the set of nodes reachable by edges of weight 1 from u in G . We call this set A_u . Now, we find the shortest path $\pi_{u,v}$ (if one exists) in $G - \{A_u\}$ from v to the output. If no unprocessed edge has such a path, then Find-Remaining-Edges terminates and the algorithm proceeds to the next level.

Otherwise, we take an edge (u, v) that minimizes the distance from v to the output in $G - \{A_u\}$. Let e be the experiment where u is fired, all nodes along

$\pi_{u,v}$ are left free, and the rest of the nodes are suppressed. We will show that $S(e)$ is enough to determine $p_{(u,v)}$. Then, the entry for this edge is marked to 0 in the table, and if it is present, is added to G . Then the algorithm continues, recomputing the sets A_u for the remaining unprocessed edges.

We now show that the value of $S(e)$, as defined above, is sufficient to learn edge (u, v) . All edges from u to π are either up edges or have already been processed by the time edge (u, v) is considered, otherwise there would be an unprocessed edge from u to a node on π with a shorter distance to the root in $G - A_u$. All edges on π in $G - C$ are known from Find-Up-Edges, and the rest of the edges are known because they are in C . Hence, by Lemma 2, we can compute the weight of edge (u, v) , and add it to G if its weight is positive.

Find-Remaining-Edges returns when all remaining unprocessed down and level pairs of nodes u, v do not have a path from v to the root in $G - A_u$. The algorithm does not attempt to learn these edges. We will argue that when an execution of Find-Remaining-Edges terminates, all of the unprocessed edges are not discoverable. Let u, v be such a pair. Let S be the graph of the complete social network and B_u be the set of nodes reachable by edges of weight 1 in S . If there is no path from v to the root in $S - B_u$, edge (u, v) is clearly not discoverable. We note that $A_u \subseteq B_u$.

By way of contradiction, we will assume there exist vertices u (on level i) and v (on level $\geq i$) such that there is a path of discoverable edges from v to the root in $S - B_u$ but not in $G - A_u$ at the time Find-Remaining-Edge exits. Once this path reaches level $i - 1$ in G , then the path can be continued by following up edges to the root. By assumption, G has all discoverable edges among the complete set C , which contains all nodes at levels $> i$. Hence, there must be some smallest set of edges U going from nodes at level i , that are in S but not in G , such that if they were added to G , then there would be a path from v to the root node in $G - A_u$. All of the edges in U must lie on a path π . Let edge $(x, y) \in U$ be the unprocessed edge closest to the root along the path. Because edge (x, y) was unprocessed, there was a path of 1 edges from x to a node in π above y ; otherwise, there would be a path from y to the root in $G - A_x$ and (x, y) would have been processed. But taking the path of 1 edges from x to a node in π gives a path from v to the root in $G - A_u$ using one fewer unprocessed edge. This contradicts that U was the smallest set of edges that, if added to G , would make a path from v to the root in $G - A_u$. This contradicts our assumption that a discoverable edge exists that Find-Remaining-Edges does not find.

To analyze number of queries used, we observe that every query either confirms the absence of an edge or discovers one. Hence, Algorithm 1 performs at most $O(n^2)$ queries.

3.1 A Matching $\Omega(n^2)$ Lower Bound

We show an information theoretic lower bound for learning social networks that matches the bound of the algorithm.

Theorem 2. $\Omega(n^2)$ queries are required to learn a social network.

Proof. We give an information theoretic lower bound. We consider the following class of graphs on vertices $\{v_1, \dots, v_{2n+1}\}$. We let v_{2n+1} be the output. The edges $(v_{n+1}, v_{2n+1}), (v_{n+2}, v_{2n+1}), \dots, (v_{2n}, v_{2n+1})$ all have weight 1. The edges $(v_1, v_{n+1}), (v_2, v_{n+2}), \dots, (v_n, v_{2n})$ also all have weight 1. For $1 \leq i \leq n$, $n+1 \leq j \leq 2n$, and $j \neq i+n$, each edge (v_i, v_j) is either present with weight 1 or absent. The rest of the edges are absent. There are $2^{\Omega(n^2)}$ such graphs and the answer to every exact value injection query is 1 bit because all present edges have weight 1. Algorithm 1 differentiates all graphs in this class because all edges in this class of graphs are up edges and are therefore discoverable. Hence, by an information theoretic lower bound, at least $\log 2^{\Omega(n^2)} = \Omega(n^2)$ queries are needed. \square

4 Trees

In this section, we will consider the special case in which the target social networks come from the class of trees. A **tree social network** is a social network whose edges are up edges that form a tree.

Theorem 3. *Learning a social network tree takes $\Theta(n \log n)$ exact value injection queries.*

Proof. We first show the lower bound. Consider a directed path of nodes, with the output node at an endpoint. All edges along the path have probability 1. The only unknown is the ordering of the nodes along the path. Let u and v be two nodes. We can test which of the two nodes has a smaller distance to the root by the experiment that fires u and suppresses v . If this fires the output, then u is closer to the root; otherwise, v is closer. Hence, all orderings can be distinguished. Because all edges have probability one, the result of any experiment is deterministically a 1 or 0, a 1-bit answer. There are $n!$ orderings of nodes. This gives an $\Omega(\log(n!)) = \Omega(n \log(n))$ information-theoretic lower bound.

We now develop an algorithm that meets this bound for trees. Let T be the target tree social network. In a tree, an **ancestor** of node u is any node on the path from u to the output. We can test whether node v is an ancestor of node u by firing u and suppressing v . If the result is > 0 , then v is not an ancestor of u . In general, to test whether there exists some node in V that is an ancestor of u , we can fire u and suppress all nodes in V . This allows us to find all k ancestors of a given node u by binary search in $O(k \log(n))$ queries. Because the ancestors of u form a path, we can sort them by their depth using $O(k \log(k))$ queries (an ancestor test involving two nodes provides a comparator) to get a directed path from u to the output.

Now, we will use the observation above to make an algorithm for reconstructing trees. We keep a graph T' that is a connected subgraph of T that we build up by adding new nodes until T' contains all the vertices in T . In attaching a new node u to T' , we first determine v , u 's deepest ancestor in T' . We can do this by recursively by splitting the nodes in T' into roughly equal halves H_1 and H_2 such that no node in H_2 is an ancestor of a node in H_1 . In one query we can test whether v is in H_1 by suppressing all nodes in H_2 and firing u ; thus, we can

find v in $\log(n)$ queries. We then find, by binary search, the set of all ancestors of u in T that are not in T' , and we sort them by their distance to the root in T . This gives a path of vertices from u to v that we can append to T' and continue this process until all the vertices are added to T' .

In adding a new node u to T' we spend $(\log(n))$ queries to find its deepest ancestor in T' , and $O(k \log(n))$ queries to add u 's $k \geq 0$ newly found ancestors to T' . This costs us an amortized $O(\log(n))$ queries per node, giving an $O(n \log(n))$ algorithm for learning the structure of the tree. We note that the structure is learned using just zero/non-zero information from the queries.

Finally, to learn the weights of the edges in the tree, because we have a shortest excitation path for each node, the edge weights can be discovered in n queries by Lemma 2. \square

5 Limitations of Excitation Paths

In this section, we construct a family of social networks in which there exists a node, that when fired, activates the output node with high probability, but any excitation path experiment for that node has an exponentially small probability of activating the output. Namely, we will prove the following theorem.

Theorem 4. *There exists a family of social networks S for which there exists a node $v \in S$ and an experiment e where only v is fired, such that for any excitation path experiment e_π for v ,*

$$S(e) = 2^{\Omega(\sqrt{n})} S(e_\pi)$$

Proof. Let $\{v_1, \dots, v_n\}$ be nodes in this network, with v_1 the output node. For all $1 < i < n-1$, let $p_{(i,i+1)} = 1$ - we call these **back edges**. For all $i, j > 0$ such that $i + j \leq n$, create a new node w_{ij} and let $p_{(w_{ij}, v_i)} = 1$ and $p_{(v_{i+j}, w_{ij})} = 2^{-j/\sqrt{n}}$.

Let e_1 be an excitation path experiment for v_n , where v_n is fired. $S(e_1)$ is the probability all edges along the path fire, which we can bound

$$\begin{aligned} S(e_1) &= \prod_{f_i: \sum f_i \geq n-1} 2^{-\frac{f_i}{\sqrt{n}}} \\ &= 2^{-\frac{\sum f_i}{\sqrt{n}}} \\ &= 2^{-\Omega(\sqrt{n})} \end{aligned}$$

The f_i 's represent the number of nodes forward their corresponding edges jump.

Let e_2 be the experiment where v_n is fired and the remaining agents are set free. We will show there exists a constant $c > 0$ such that $S(e_2) \geq c$.

We consider e_2 . The probability that v_n does not fire any other nodes is $\prod_{i=1}^n (1 - 2^{-i/\sqrt{n}})$. Now, we can bound the probability of the root firing. Let $T(i)$ be the probability the root becomes activated given v_i has fired. We set up

a recurrence

$$T(1) = 1$$

$$T(n) \geq \left(1 - \prod_{i=1}^{n-1} \left(1 - \frac{1}{2} \frac{i}{\sqrt{n}}\right)\right) T(n-1)$$

Where we have an inequality above because if v_n activates any other node, then v_{n-1} becomes activated due to the back edges.

Thus, $T(n) \geq \left(1 - \frac{1}{2} \frac{\sqrt{n}}{\sqrt{n}}\right) T(n-1)$ because the first \sqrt{n} terms of the product above are $\leq 1/2$. Unraveling the recurrence, we get

$$T(n) \geq \prod_{i=1}^{n-1} \left(1 - \frac{1}{2} \frac{\sqrt{i}}{\sqrt{i}}\right),$$

We know $\lim_{n \rightarrow \infty} T(n) > 0$ if $\sum_{i=1}^{\infty} \frac{1}{2} \frac{\sqrt{i}}{\sqrt{i}}$ converges. By the Cauchy Condensation Test, $\sum_{i=1}^{\infty} \frac{1}{2} \frac{\sqrt{i}}{\sqrt{i}}$ converges if and only if $\sum_{i=1}^{\infty} 2^n \frac{1}{2} \frac{\sqrt{2^n}}{\sqrt{2^n}}$ converges [14]. The ratio test easily tells us that $\sum_{i=1}^{\infty} 2^n \frac{1}{2} \frac{\sqrt{2^n}}{\sqrt{2^n}}$ converges. Therefore, there exists a constant $c > 0$ such that $\forall n T(n) \geq c$. \square

This example shows that many paths, each of which has an exponentially small effect on the output, can add up to have a detectable effect on the output. When using non-exact value injection queries, the goal is to learn a circuit to approximate behavioral equivalence. Yet this example shows us that if the learner has access to only non-exact value injection queries, then to learn this circuit by only path based methods like our algorithms do, one would need an exponential number of experiments to detect the effect on the output. This implies that for non-exact value injection queries, either the circuits would need a depth limitation, or non path-based algorithms would need to be developed.

6 Finding Small Influential Sets of Nodes

We now examine a seemingly easier problem. Instead of learning the entire social network, we consider the task of finding a small set of influential nodes. More formally, let $I \subset V$ such that $v_n \notin I$, and let e_I be the experiment where all nodes in I are fired and the rest are left free. I has **influence** p if $S(e_I) \geq p$; we call such a set **influential**. We first show that it is NP-Hard to find the smallest set of certain influence, even if the structure of the network is known.

Theorem 5. *Given a social network S of size n and a threshold probability p , it is NP-Hard to approximate the size of the smallest set of nodes having influence p within $o(\log(n))$.*

Proof. We reduce from Set Cover. Take an instance of Set Cover with points $\{x_1, \dots, x_k\}$ and sets $\{X_1, \dots, X_l\}$. In the social network S , we create a nodes $\{v_1, \dots, v_k\}$ for the points and $\{w_1, \dots, w_l\}$ for the sets in the original Set Cover instance. If point x_i belongs to set X_j , we make an edge from w_j to v_i with associated probability of 1. We set the influence threshold parameter p to $\frac{1}{2}$. We run edges from all nodes v_i to the output, all with associated probability = $1 - \frac{1}{2}^{1/k}$. Activating a node w_i corresponds to choosing the set X_i and activating a node v_i corresponds to choosing an arbitrary set X_j that contains x_i . The output will fire with probability $\geq \frac{1}{2}$ only if all of the v_i 's fire. This completes the reduction. Because Set Cover is NP-Hard to approximate to within $o(\log n)$ [13], so is approximating the size of the smallest influential set. \square

Theorem 6. *Let S be a social network of size n and let I be the smallest set of nodes having influence p , where $m = |I|$. We can find a set of nodes of size $m \log(p/\epsilon)$ of influence $(p-\epsilon)$ using $O(nm \log(p/\epsilon))$ exact value injection queries.*

Proof. Consider Algorithm 3.

Algorithm 3 An Algorithm for Finding a Set of Influential Nodes

Let S be the target social network.
Let p be the threshold probability.
Let ϵ be the error tolerance.
Let $I = \emptyset$.
Let e_I be the experiment where all nodes in I are fired, and the rest are left free.
while $S(e_I) < p - \epsilon$ **do**
 Let $v = \arg \max_{v_j \in V} S(e_I|_{v_j=1})$
 $I = I \cup \{v\}$
end while
Return I

Assume the optimal solution X , where $S(e_X) \geq p$, has size m . We claim that at any stage of the algorithm, if $S(e_I) < p - \epsilon$, greedily adding one more node w to I makes

$$S(e_{I \cup \{w\}}) \geq S(e_I) + \frac{p - S(e_I)}{m}.$$

We can see this by noting that there exists a set of at most m nodes, namely X , that will get the probability all the way to p . By Lemma 3, some node will get us at least $\frac{1}{m}$ th of the way there.

Let k be the number of rounds this algorithm is run. We look at the difference between p and $S(e_I)$ after k rounds. By the observation above, we can compute the number of rounds to get the difference to within ϵ . For

$$p \left(1 - \frac{1}{m}\right)^k < \epsilon$$

it suffices that $k > m \log\left(\frac{p}{\epsilon}\right)$. Therefore, after $m \log\left(\frac{p}{\epsilon}\right)$ rounds, $S(e_I)$ is within ϵ of p . We check $O(n)$ nodes each round, making for $O(nm \log\left(\frac{p}{\epsilon}\right))$ queries. \square

We now reconcile the algorithm and the hardness of approximation result. Given a social network created by the Set Cover reduction from Theorem 5, we can try to learn the influential nodes using Algorithm 3. If we set

$$\epsilon = \frac{1}{2} - \frac{1}{2} \frac{1}{n-1} = \Theta\left(\frac{1}{n^2}\right),$$

this makes ϵ small enough to force the algorithm to cover all of the v_i 's. It would find a set of $(m \log(pn^2)) = O(m \log(n))$ nodes having influence p , which gives a $O(\log(n))$ approximation and matches the lower bound. It is worth noting that the greedy algorithm for Set Cover also matches its hardness of approximation lower bound [15].

We will use Lemma 3, a version of which is derived in [10]. A function f is **submodular** if $f(A \cup \{x\}) - f(A) \geq f(B \cup \{x\}) - f(B)$ whenever $A \subseteq B$.

Lemma 3. $S(e_I)$ is a positive monotone, submodular function of I . [10]

Corollary 1. If p is the maximum influence of any k node set in the network, then Algorithm 3, with a threshold of 1, terminated after k steps, produces a set with influence $\geq (1 - \frac{1}{e})p$.

Proof. Nemhauser et al. [12] show that greedily maximizing a non-negative, monotone, submodular function on sets gives a $(1 - \frac{1}{e})$ approximation to the function on k -element sets. Hence, this follows from Lemma 3. \square

7 Open Problems

We leave open a number of interesting and challenging problems. Our results rely on exact value injection queries. While these queries are theoretically elegant, in real-world applications learners would normally only have access to non-exact value injection queries, and for such queries our algorithms would need to be modified, mainly because we look for shortest paths, not necessarily the paths least diluted by the multiplication of probabilities. The Angluin et al. [2] results on probabilistic networks adapt some exact value injection query algorithms to work in non-exact settings, yet we see no clear way of similarly modifying our algorithms. Furthermore, in moving to the non-exact setting, because of the results from Section 5, either target network depth would need to be limited, or algorithms would have to be invented that do not rely on excitation paths.

Another interesting topic to explore is what other classes of cyclic networks can be learned using similar algorithms? Our algorithms rely on the independence assumption in the independent cascade social network model. However, there are other more general models of social networks, like the **decreasing cascade model** [10]. It would be worthwhile exploring their learnability as well.

Finally, it is often the case that graph algorithms run faster on sparse graphs. It would be interesting to design an algorithm for learning social networks whose query complexity was a function of the size of the edge set in the target graph.
